## Abstract

In the same way that the computer vision (CV) and natural language processing (NLP) communities have developed self-supervised methods, reinforcement learning (RL) can be cast as a self-supervised problem: learning to reach any goal, without requiring human-specified rewards or labels. However, actually building a self-supervised foundation for RL faces some important challenges. Building on prior contrastive approaches to this RL problem, we conduct careful ablation experiments and discover that a shallow and wide architecture, combined with careful weight initialization and data augmentation, can significantly boost the performance of these contrastive RL approaches on challenging simulated benchmarks. Additionally, we demonstrate that, with these design decisions, contrastive approaches can solve real-world robotic manipulation tasks, with tasks being specified by a single goal image provided after training.<sup>1</sup>

## 1 Introduction

Self-supervised learning serves as the bedrock for many NLP and computer vision applications, leveraging unlabeled data to acquire good representations for downstream tasks. How might we enable similar capabilities for RL algorithms? In NLP and computer vision, self-supervised learning is typically done via one objective (often denoising), while the downstream tasks use a different objective (e.g., linear regression). In the RL setting, this coupling can be made even tighter by using a single objective to simultaneously result in the acquisition of good representations and the learning of goal-reaching policies (assisted by those representations). This formulation obviates the need for manual reward specification while also providing a theoretically-grounded way of choosing the self-supervised learning objective.

However, actually implementing a goal-conditioned RL system that realizes this promise has remained challenging for several reasons. First, it requires that a single self-supervised objective drive two separate learning processes: the acquisition of good representations, and the learning of the corresponding policies. Since the policies learned depend on the representations, failing to learn good representations will make it challenging (or perhaps impossible) to learn good goal-reaching policies. Second, because much of the work on self-supervised learning has been focused on CV and NLP, not RL, the recent innovations in those fields may not transfer to the RL setting; the best objectives, architectures, and regularizers for the RL setting may be considerably different from the best choices in other fields. Third, the right representations for the RL setting will need to capture nuanced and detailed information not only about the environment dynamics, but also about what states may lead to certain goal states. This is in contrast to typical representations from computer vision, which mostly reason about the relationship between objects in a static image (e.g., for classification or segmentation). Nonetheless, this third challenge also presents an intriguing opportunity: the

---

representations learned via a self-supervised RL algorithm might capture information not just about images themselves, but about the underlying *decision making problem*; they may tell us not only what is contained within an image, but how to generate a plan for reaching other images.

In this paper, we will focus on self-supervised RL methods that solve goal-conditioned RL tasks using contrastive learning. We will refer to these methods as *contrastive RL* [22, 24, 35, 99]. We study what is required to stabilize these contrastive RL methods, focusing both on their *learned representations* and their *learned policies*. The aim is to understand what representations these methods learn, how their policies perform, and what ingredients are required to stabilize these methods in highly-complex, image-based offline RL tasks. One key finding is that a set of novel design decisions concerning the implementation of contrastive RL algorithms; we refer to our effective implementation as **stable contrastive RL**. We find that decisions regarding model capacity and regularization exert a high degree of influence of the performance of the resulting policies; our design decisions result in a +45% median improvement over prior implementations of contrastive RL, and a 2 $\times$  median improvement relative to alternative goal-conditioned RL methods. We also demonstrate the superior performance of contrastive RL methods on real-world robotic manipulation tasks. This finding motivates us to study representations, which we find not only capture information about what is contained within a single image observation, but also about how one observation can be reached from another: interpolating between representations corresponds to planning (see Fig. 6). We also discuss a theoretical connection between contrastive RL methods and hard negative mining, helping to explain the success of these methods (see Sec. 4 & 5.5).

## 2 Related Work

This paper will build upon prior work on self-supervised RL, a problem that has been widely studied in the contexts of goal-conditioned RL, representation learning, and model learning. The aim of this paper is to study what design elements are important for unlocking the capabilities of one promising class of self-supervised RL algorithms.

**Goal-conditioned RL.** Our work builds upon a large body of prior work on goal-conditioned RL [50, 83], a problem setting that is appealing because it can be formulated in an entirely self-supervised manner (without human rewards) and allows users to specify tasks by simply providing a goal image. Prior work in this area can roughly be categorized into conditional imitation learning methods [15, 33, 36, 59, 91] and actor-critic methods [22, 24]. While in theory these self-supervised methods should be sufficient to solve arbitrary goal-reaching tasks, prior work has found that adding additional representation losses [68, 70], planning modules [8, 25, 82], and curated training examples [9, 97] can boost performance. Our paper investigates where these components are strictly necessary, or whether their functions can emerge from a single self-supervised objective.

**Representation Learning in RL.** Learning compact visual representations is a common way of incorporating offline data into RL algorithms [3, 6, 61, 69, 86, 93, 102, 108]. Some prior methods directly use off-the-shelf visual representation learning components such as perception-specific loss [28, 56, 92, 106] and data augmentation [57, 58, 77, 110] to learn these representations; other work uses representation learning objectives tailored to the RL problem [1, 13, 29, 32, 41, 78, 90, 117]. While these methods have achieved good results and their modular design makes experimentation easier (no need to retrain the representations for each experiment), they decouple the representation learning problem from the RL problem. Our experiments will demonstrate that the decoupling can lead to representations that are poorly adapted for solving the RL problem. With proper design decisions, self-supervised RL methods can acquire good representations on their own.

**Model Learning in RL.** Another line of work uses offline datasets to learn an explicit model. While these methods enable one-step forward prediction [38, 64, 103] and auto-regressive imaginary rollouts [18, 27, 68, 94, 113] that is a subset of the more general video prediction problem [14, 55, 63], model outputs usually degrade rapidly into the future [48, 115]. In the end, fitting the model is a self-supervised problem, actually using that model requires supervision for planning or RL. Appendix A compares these prior methods.

### 3 Contrastive RL and Design Decisions

In this section we introduce notations and the goal-conditioned RL objective, and then revise a prior algorithm that we will use in our experiments, mentioning important design decisions.

#### 3.1 Preliminaries

We assume a goal-conditioned controlled Markov process (an MDP without a reward function) defined by states  $s_t \in \mathcal{S}$ , goals  $g \in \mathcal{G}$ , actions  $a_t$ , initial state distribution  $p_0(s_0)$  and dynamics  $p(s_{t+1} | s_t, a_t)$ . We will learn a goal-conditioned policy  $\pi(a | s, g)$ , where the state  $s$  and the goal  $g$  are both RGB images. Given a policy  $\pi(a | s, g)$ , we define  $\mathbb{P}^{\pi(\cdot|s,g)}(s_t = s | s_0, a_0)$  as the probability density of reaching state  $s$  after exactly  $t$  steps, starting at state  $s_0$  and action  $a_0$ . The discounted state occupancy measure is a geometrically-weighted average of these densities:

$$p^{\pi(\cdot|s,g)}(s_{t+} = s | s_0, a_0) \triangleq (1 - \gamma) \sum_{t=0}^{\infty} \gamma^t \mathbb{P}^{\pi(\cdot|s,g)}(s_t = s | s_0, a_0). \quad (1)$$

The policy is learned by maximizing the likelihood of reaching the desired goal state under this discounted state occupancy measure [22, 24, 81, 99]:

$$\max_{\pi(\cdot|s,g)} \mathbb{E}_{p_g(g)}[p^{\pi(\cdot|s,g)}(s_{t+} = g)] = \mathbb{E}_{p_g(g)p_0(s_0)\pi(a_0|s_0,g)} \left[ p^{\pi(\cdot|s,g)}(s_{t+} | s_0, a_0) \right].$$

Following prior work [24], we estimate this objective via contrastive representation learning [37]; we will learn a critic function that takes a state-action pair  $(s, a)$  and a future state  $s_{t+}$  as input, and outputs a real number  $f(s, a, s_{t+})$  estimating the (ratio of) likelihood of reaching the future state, given the current state and action. We will parameterize the critic function as an inner product between the state-action representation  $\phi(s, a)$  and the future state representation  $\psi(s_{t+})$ ,  $f(s, a, s_{t+}) = \phi(s, a)^T \psi(s_{t+})$ , interpreting the critic value as the similarity between those representations.

Contrastive RL distinguishes a future state sampled from the average discounted state occupancy measure,  $s_f^+ \sim p^{\pi(\cdot|s,g)}(s_{t+} | s, a) = \int p^{\pi(\cdot|s,g)}(s_{t+} | s, a) p^\pi(g | s, a) dg$ , from a future state sampled from an arbitrary state-action pair,  $s_f^- \sim p(s_{t+}) = \int p^{\pi(\cdot|s,g)}(s_{t+} | s, a) p(s, a) ds da$ , using the NCE-Binary [37, 47, 62] objective:

$$\max_{\phi, \psi} \mathcal{L}(s, a; \phi, \psi) \triangleq \mathbb{E}_{s_f^+ \sim p^{\pi(\cdot|s,g)}(s_{t+}|s,a)} \underbrace{[\log \sigma(\phi(s, a)^T \psi(s_f^+))]}_{\mathcal{L}_1(\phi(s,a), \psi(s_f^+))} + \mathbb{E}_{s_f^- \sim p(s_{t+})} \underbrace{[\log(1 - \sigma(\phi(s, a)^T \psi(s_f^-)))]}_{\mathcal{L}_2(\phi(s,a), \psi(s_f^-))}. \quad (2)$$

This objective can also be formulated in an off-policy manner (see Eysenbach et al. [22] and Appendix B); we will use this off-policy version in our experiments.

#### 3.2 Design Decisions for Stabilizing Contrastive RL

In this section, we describe the most important design factors to stabilize contrastive RL: (i) using appropriate encoder architecture and batch size, (ii) stabilizing and speeding up training with layer normalization and cold initialization, and (iii) combating overfitting with data augmentation.

**Neural network architecture for image inputs.** In vision and language domains, scaling the architecture size has enabled large neural networks to achieve ever higher performance on ever larger datasets [6, 7, 16, 76, 96]. While large vision models (e.g., ResNets [46] and Transformers [101]) have been adopted to the RL setting [10, 21, 49, 54, 87], shallow CNNs remain pervasive in RL [5, 39, 40, 57, 58, 84], suggesting that simple architectures might be sufficient. In our experiments, we will study two aspects of the architecture: the visual feature extractor, and the contrastive representations learned on top of these visual features. For the visual feature extractor, we will compare a simple *CNN* versus a much larger *ResNet*. For the contrastive representations, we will study the effect of scaling the width and depth of these MLPs. While prior methods often train the visual feature extractor separately from the subsequent MLP [76], our experiments will also study end-to-end training approaches. Appendix C includes an overview of our network architecture.

**Batch size.** Prior works in computer vision have found that contrastive representation learning benefits from large batch sizes, which can stabilize and accelerate learning [11, 12, 34, 45]. In the context of contrastive RL, using larger batches increases not only the number of positive examples (linear in batch size) but also the number of negative examples (quadratic in batch size). This means that algorithm would be able to see more random goals  $s_f^-$  given a future goal  $s_f^+$ . We will study how these growing positive and negative examples as a result of growing batch sizes will affect contrastive RL.

**Layer normalization.** We conjecture that learning from a *diverse* offline dataset, containing examples of various manipulation behaviors, may result in features and gradients that are different for different subsets of the dataset [114]. We will study whether adding layer normalization [4] to the visual feature extractor and the subsequent MLP can boost performance. We will experiment with applying layer normalization to every layer of both CNN and MLP, before the non-linear activation function.

**Cold initialization.** Prior work has proposed that the alignment between positive examples is crucial to contrastive representation learning [104]. To encourage the alignment of representations during the initial training phase, we will weight initialization of the final feed-forward layer. Precisely, we will initialize the weights in the final layers of  $\phi(s, a)$  and  $\psi(g)$  using UNIF $[-10^{-12}, 10^{-12}]$ , resulting in representations that remain close to one another during the initial stages of learning. We will compare this “cold initialization” approach to a more standard initialization strategy, UNIF $[-10^{-4}, 10^{-4}]$ .

**Data augmentation.** Following prior work [6, 24, 30, 67, 74, 88, 105], we will augment the actor objective to include an additional behavioral cloning regularizer, which penalizes the actor for sampling out-of-distribution actions. While most of our design decisions increase the model capacity, adding this behavioral cloning acts as a sort of regularization often important in the offline RL setting to avoid overfitting [30]. Initial experiments found that this regularizer itself was prone to overfitting, motivating us to investigate data augmentation (random cropping), similar to prior work in offline RL [42, 57, 111].

## 4 A Connection Between Contrastive RL and Hard Negative Mining

When learning contrastive representations using the NCE-binary loss, we want to relate positive examples with similar representations and relate negative examples with dissimilar representations [104]. Assigning dissimilar representations to negative examples is a big challenge in contrastive learning and deep metric learning [43, 89, 107]. One common solution to this problem is hard negative mining [17, 31, 79, 85, 95, 118] – sampling those negative examples that are difficult to discriminate for the current representations. Prior works have found that introducing hard negative mining can boost the performance of contrastive learning, even on goal-conditioned RL [80, 97]. However, hard negative mining requires additional hyperparameters and privileged knowledge (e.g., accessing position of robot arm in the environment [97]), and makes it less clear what objective is being optimized.

Here, we show how the NCE-binary contrastive objective in contrastive RL already induces a sort of hard negative mining. We start by analyzing the gradient of the MC objective (Eq. 2). Optimizing this objective with respect to the representation of random goals  $\psi(s_f^-)$  yields a gradient which “pushes away” negative examples:

$$\frac{\partial}{\partial \psi(s_f^-)} \mathcal{L}_2(\phi(s, a), \psi(s_f^-)) = -\sigma(\phi(s, a)^\top \psi(s_f^-)) \phi(s, a).$$

Intuitively, this gradient resembles hard negative mining in the sense that we push the representation of a random goal  $\psi(s_f^-)$  away from the anchor  $\phi(s, a)$  with a larger weight when it is misclassified. This intuition explains why we expect that large batch sizes will be important: it will strengthen the effect of this (implicit) hard negative mining by providing a large pool of examples from which identify misclassified examples.

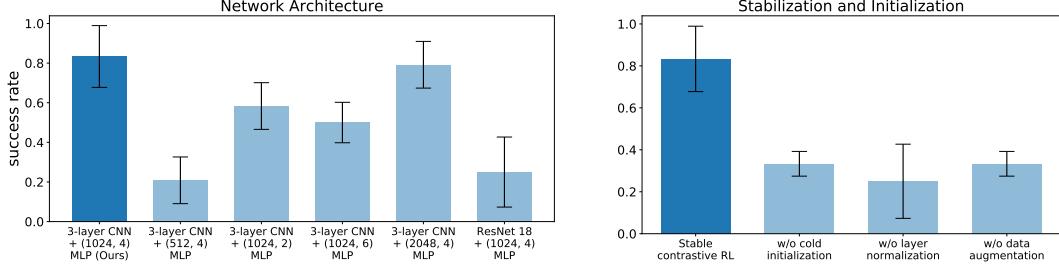

Figure 1: **Importance of architecture initialization, and normalization.** (*Left*) Our experiments suggest that using a deep CNN *decreases* performance, but using a wide MLP is important. (*Right*) The good performance of our implementation depends on “cold initialization”, layer normalization, and data augmentation. Prior work [24] uses an even smaller network architecture (256, 2) and none of the stabilization/initialization decisions.

## 5 Experiments

Our experiments start with studying design decisions that drive stable contrastive RL and use simulated and real-world benchmarks to compare contrastive RL to other offline goal-conditioned policy learning methods, including those that use conditional imitation and employ representation pre-trained by auxiliary objectives. We then analyze unique properties of the representations learned by stable contrastive RL, providing an empirical verification of the connection drawn in Sec. 4. Finally, we conduct various ablation studies to test the generalizing and scalability of our algorithm.

### 5.1 Experimental Setup

Our experiments use a suite of simulated and real-world goal-conditioned control tasks based on prior work [19, 25, 26, 65]. *First*, we will use a benchmark of five manipulation tasks proposed in [25, 26] (Fig. 2), which entail controlling a simulated robot arm to rearrange various objects. The observations and goals are  $48 \times 48 \times 3$  RGB images of the current scene. For evaluation, we create a dataset of 50 goals by randomly sampling the positions of objects and the robot arm, and we evaluate the success rate of reaching these goals. These evaluation goals are not revealed during training; the actor is trained using goals randomly sampled from other trajectories in the training dataset.

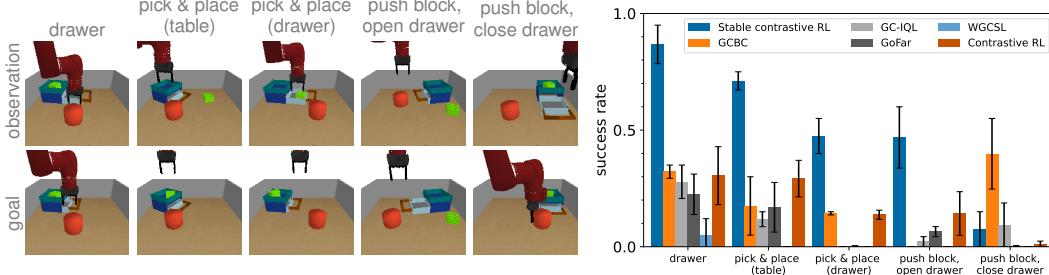

*Second*, we will use the goal-conditioned locomotion benchmark proposed in [65]. These tasks entail reaching desired poses, such as controlling a biped to perform a headstand or controlling a quadruped to balance on two feet. While the manipulation benchmark consists primarily of near-optimal data, the locomotion benchmark includes a mixture of optimal and suboptimal transitions, collected from the replay buffer of a policy trained with LEXA [65], which achieves a success rate of 67% at convergence.

*Third*, we will study whether good performance on these simulated benchmarks translates to real-world success using a 6-DOF WidowX 250 robot arm. We train on an expanded version of the Bridge dataset [19] which entails controlling that robot arm to complete different housekeeping tasks, such as pushing pans and cloth sweeping. The dataset also includes suboptimal trajectories collected by a weak scripted pick and place policy that often misses grasping the objects. For evaluation, we use three tasks that are seen in the dataset, though we slightly vary the initial and desired object positions (see Fig. 5). See Appendix D for details of the task and dataset.

### 5.2 Ablation Study

The good performance of contrastive RL depends on a few key design decisions. In this section, we aim to understand how special architectures and initializations can stabilize and accelerate contrastive RL in the offline setting. We will use the easiest task, `drawer`, to conduct all the ablation experiments. The Appendix contains additional experiments underscoring the importance of large batches (Appendix E.9) and showing that lower-dimensional representations achieve higher success rates (Appendix E.11).

**Network architecture.** We study the architectures for the image encoder and the subsequent MLP. For the image encoder, we compare a shallow 3-layer CNN (similar to DQN [66]) to a ResNet 18 [46]. Fig 1 (*Left*) shows that 3-layer CNN encoder outperforms ResNet 18 encoder by  $2.89 \times$  (81% vs. 28%), perhaps because the over-parameterized ResNet 18 is liable to overfit to the offline dataset. We

**Figure 2: Evaluation on simulated manipulation tasks.** (Left) The five simulated evaluation tasks, with examples of the initial observation (top) and goal observation (bottom). (Right) Stable contrastive RL outperforms all baselines on  $\frac{4}{5}$  tasks, often by a large margin. The comparison with “contrastive RL” underscores the importance of our design decisions.

then study the architecture of the subsequent MLP, denoted as (width, depth). Our experiments show that a (1024, 4) MLP yields the best result, suggesting that wider MLPs perform better. In subsequent experiments, we use the 3-layer CNN as the visual feature extractor followed by a (1024, 4) MLP.

**Stabilization and initialization.** We hypothesize that layer normalization balances feature magnitude and prevents gradient interference, while data augmentation mitigates overfitting. Our experiments in Fig. 1 (Right) suggest that both layer normalization and data augmentation (via random cropping) are critical for good performance.

We next study weight initialization, using the “cold initialization” strategy outlined in Sec. 3.2. We find that this strategy, which uses very small initial weights  $\text{UNIF}[-10^{-12}, 10^{-12}]$ , boosts performance by 2.49 times (82% vs. 33%) than the initialization strategy  $\text{UNIF}[-10^{-4}, 10^{-4}]$ . Additional experiments in Appendix Fig. 23 show that  $\text{UNIF}[-10^{-8}, 10^{-8}]$  and  $\text{UNIF}[-10^{-16}, 10^{-16}]$  achieve only slightly worse results than  $\text{UNIF}[-10^{-12}, 10^{-12}]$ . In Appendix E.10, we show a smaller learning rates and a learning rate “warmup” have a different (worse) effect than cold initialization. Results from these ablation experiments encourage us to apply layer normalization, data augmentation, and cold initialization in other experiments.

**Summary.** Our experiments suggest the following design decisions stabilizing contrastive RL: (i) Using a simple 3-layer CNN visual feature extractor followed by a wide MLP. (ii) Add layer normalization. (iii) Initialize last-layer weights of the MLP with small values,  $\text{UNIF}[-10^{-12}, 10^{-12}]$ . (iv) Apply random cropping to both the state and goal images. (v) Use a large batch size (2048). We use **stable contrastive RL** to denote this combination of design decisions.

### 5.3 Comparing to Prior Methods

Next, we study the efficacy of stable contrastive RL comparing to prior methods, including those that goal-conditioned supervised learning and those that employ auxiliary representation learning objectives. We run experiments on datasets collected from both simulation and the real-world without any interaction with the environment during training – that is, all experiments focus on offline, goal-conditioned RL.

**Simulation evaluation – manipulation.** We first compare to five baselines that build on goal-conditioned behavioral cloning. The simplest goal-conditioned behavioral cloning (“GCBC”) [10, 15, 20, 33, 59, 72, 91] trains a policy to conditionally imitate trajectories reaching goal  $g$ . Goal-conditioned IQL (GC-IQL) is a goal-conditioned version of IQL [53], a state-of-the-art offline RL algorithm. GoFar [60] is an improvement of GCBC that weights the log likelihood of actions using a learned critic function. The fourth baseline is WGCSL [109], which augments GCBC with discounted advantage weights for policy regression. We also include a comparison with contrastive RL [24], which helps us test whether those design decisions improve the performance. Like stable contrastive RL, these baselines are all trained directly on goal images in an end-to-end fashion, not using any explicit feature learning. As shown in Fig. 2, stable contrastive RL matches or surpasses all baselines on four of the five tasks. On those more challenging tasks (push block, open drawer; pick & place (table); pick & place (drawer)), we see a marked difference between these baselines and stable contrastive RL. However, the baseline methods fail to solve these more challenging tasks. Note that stable contrastive RL fails to exceed GC-IQL and GCBC on one of the tasks (push block, close drawer), perhaps because of the significantly dissimilar camera angles.

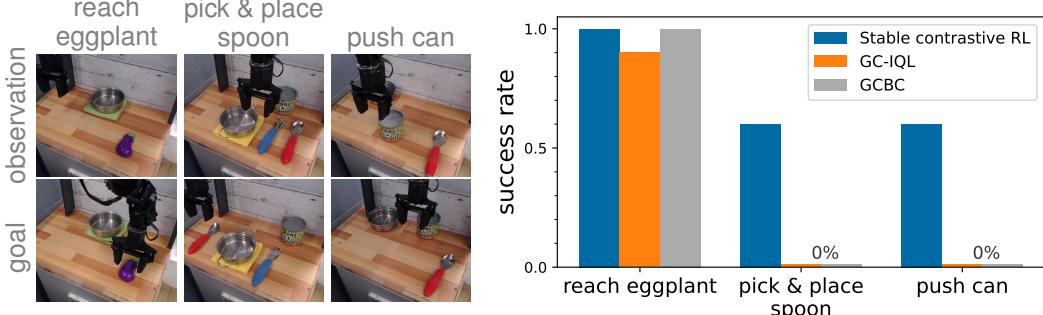

Figure 5: **Evaluation on real manipulation tasks.** Stable contrastive RL matches or outperforms GC-IQL and GCBC on all manipulation tasks. Each success rate is calculated from taking 10 rollouts.

We next compare to three methods that employ learning policy on top of pre-trained representations. PTP [25] focuses on finding sub-goals in a pre-trained VQ-VAE [100] representation space and learns a policy to reach them sequentially. We also compare to a variant of GCBC learning on top of features from VIP [61]. We call this method VIP-GCBC. Similarly, our third baseline, R3M-GCBC, trains a policy via supervised learning on top of representations learned by R3M [69]. Results in Fig. 3 show that stable contrastive RL outperforms all baselines on  $\frac{4}{5}$  tasks. While the baselines all require separate objectives for RL and representation learning, stable contrastive RL achieves excellent results without the need for an additional representation learning objective. The full curves can be found in Appendix E.4. Appendices E.7 and E.8 show comparisons against an end-to-end version of PTP and to a variant without sub-goal planning.

**Simulation evaluation – locomotion.** Our next set of experiments focus on locomotion tasks. We conduct these experiments to see whether the same design decisions are helpful on tasks beyond manipulation, and on tasks from which we have only suboptimal data. We compare stable contrastive RL against contrastive RL, GCBC, and GC-IQL on two goal-reaching tasks from prior work [65]: Walker and Quadruped. We evaluate all methods in the offline setting, recording the average success rates over reaching 12 unique goal poses. As shown in Fig. 4, stable contrastive RL outperforms all three baselines on both locomotion tasks, achieving a 33% higher (relative) average success rate than the strongest baseline.

**Real-world evaluation.** We next study whether these methods can effectively solve real world, goal-directed, image-based manipulation tasks, learning entirely from offline data. We compare stable contrastive RL against the strongest performing baseline from the simulated results, GCBC. We compare to GC-IQL as well because it performed well in the simulated experiments, and its simplicity makes it practically appealing. We evaluated on three goal-reaching tasks and report success rates in Fig. 5. Stable contrastive RL performs similarly to baselines on the simple (reach eggplant) task, while achieving a 60% success rate on the two harder tasks (pick & place spoon, push can), where all baselines fail to make progress. We conjecture that this good performance might be explained by the hard-negative mining dynamics of stable contrastive RL, which are unlocked by our design decisions.

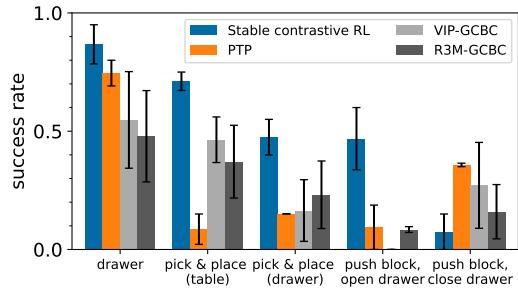

Figure 3: **Comparing to pretrained representations.** On  $\frac{4}{5}$  tasks, stable contrastive RL outperforms baselines that use frozen representations from a VAE (PTP [25]), VIP [61], and R3M [69].

On  $\frac{4}{5}$  tasks, stable contrastive RL outperforms baselines that use frozen representations from a VAE (PTP [25]), VIP [61], and R3M [69].

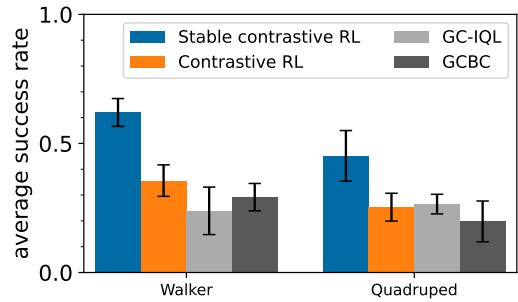

Figure 4: **Evaluation on simulated locomotion tasks.** Stable contrastive RL outperforms contrastive RL, GC-IQL and GCBC in two locomotion tasks. Each success rate is calculated by averaging over 12 diverse goal poses.

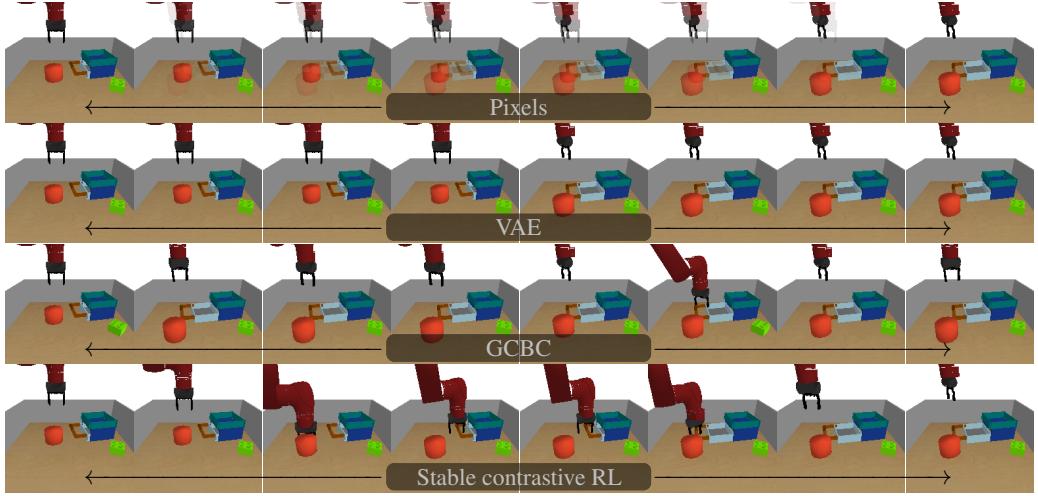

Figure 6: **Visualizing the representations.** (Row 1) Directly interpolating between two images in pixel space results in unrealistic images. (Row 2) Using a VAE, we interpolate between the representations of the left-most and right-most images, visualizing the nearest-neighbor retrievals from a validation set. The VAE captures the contents of the images but not the causal relationships – the object moves without being touched by the robot arm. (Row 3) GCBC also produces realistic images while ignoring temporal causality. (Row 4) Stable contrastive RL learns representations that capture not only the content of the images, but also the causal relationships – the arm first moves *away* from its position in the goal state so that it can move the object into place.

#### 5.4 Latent Interpolation

Self-supervised learning has achieved remarkable success in learning representations for image and representation data [11, 71, 98]. While auxiliary losses or data augmentation improve reconstruction and robustness of the learned representation, we hypothesize that representation acquired by self-supervised RL approach contains task-specific information. To answer this question, we visualize the representations learned by stable contrastive RL, a VAE, and GCBC on the push block, open drawer task. Given an initial image (Fig. 6 far left) and the desired goal image (Fig. 6 far right), we interpolate between the representations of these two images, and retrieve the nearest neighbor in a held-out validation set. For comparison, we also include direct interpolation in pixel space. As expected, interpolating in pixel space generates unrealistic images. While linearly interpolating in the VAE and GCBC representation spaces produce realistic images, the retrieved images fails to capture causal relationships, motivating the necessity of adding other machinery, e.g., relabeling latent goal [68, 75, 80] and latent sub-goal planning with value constraints [25, 26]. When interpolating the representations of stable contrastive RL, the intermediate representations correspond to sequence of observations that the policy should visit when transitioning between the initial observation and the final goal. Appendices E.1 and E.2 contain a quantitative experiment and additional visualizations.

#### 5.5 Tackling the Arm Matching Problem

Previous works have found that some goals are easier to be distinguish from the others (easy negative examples) [2, 80, 97], while some goals might require temporal-extended reasoning to reach (hard negative examples). For example, on task push block, open drawer, prior goal-conditioned algorithms [25, 53] simply match the arm position with the one in the goal image and fail to move the green block to its target position. We call this failure *the arm matching problem*. Our theoretical analysis in Sec. 4 suggests that contrastive approaches should perform this sort of hard negative mining and avoid the arm matching problem.

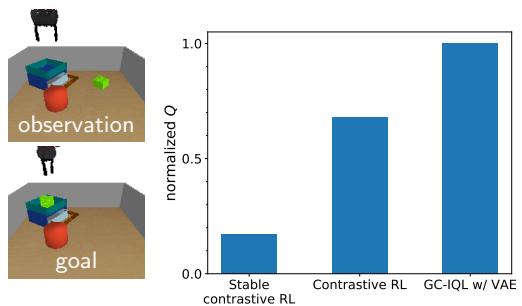

Figure 7: **Misclassifying success.** GC-IQL mistakenly predicts that this observation has succeeded in reaching this goal, even though the object is in the incorrect position. In contrast, stable contrastive RL recognizes that this observation is far from the goal and assigns it a low Q value.

We test this hypothesis in Fig. 7 by comparing the Q values learned by stable contrastive RL and contrastive RL, aiming to assess whether our design decisions lead to more accurate estimates of the Q-values. Prior work has suggested that pre-trained VAE representations can also be effective, so we also compare to a version of GC-IQL applied on top of VAE features [25, 26]. We normalize these Q values by the minimum and maximum values in a rollout. Fig. 7 compares the Q values for an observation where the object is not in the correct location, but the gripper is in the correct position. GC-IQL (mistakenly) assigns high Q values to this observation. In contrast, stable contrastive RL predicts a small value for this observation, highlighting the accuracy of its Q function and showing how it can avoid arm matching behavior. Appendix E.3 includes a comparison of Q values in an optimal trajectory.

## 5.6 The Influence of Dataset Size on Performance

Scaling model performances with the amount of data have been successfully demonstrated in CV and NLP [7, 44], motivating us to study whether contrastive RL offers similar scaling capabilities in the offline RL setting. To answer this question, we run experiments with dataset sizes increasing from 100K to 1M, comparing stable contrastive RL against a baseline that uses pre-trained features. This baseline uses the additional data purely for improving the reactive policy learned on top of pre-trained representations. The fact that this baseline doesn't improve suggests that most of the gains observed for stable contrastive RL may be coming from better representations, rather than from a better reactive policy. Results in Fig. 8 shows that stable contrastive RL effectively makes use of additional data, with a success rate that increases by 3 $\times$  as we increase the dataset size. In contrast, the performance of PTP saturates around 250K transitions, suggesting that most of the gains observed for stable contrastive RL may be coming from better representations, rather than from a better reactive policy. In Appendix E.5, we also find that the binary accuracy of the stable contrastive RL (measured on predicting the future) increases with dataset size, suggesting that the method benefits from a more diverse pool of positive and negative examples.

## 5.7 Generalizing to Unseen Tasks

Our next set of experiments study the robustness of stable contrastive RL. We hypothesize that stable contrastive RL might generalize to unseen tasks reasonably well for two reasons: (1) stable contrastive RL resembles the contrastive auxiliary objectives used by prior work to improve robustness [57, 58, 69]; (2) because stable contrastive RL learns features solely with the critic objective, we expect that the features will not retain task-irrelevant information (unlike, say, representation based on auto-encoding). We run an experiment comparing the generalization of stable contrastive RL against a baseline that uses features pre-trained via reconstruction by varying the environment. We show results on varying pitch in Fig. 9, and include the other results and full details in Appendix E.6. These experiments provide preliminary evidence that contrastive representations might generalize reasonably well.

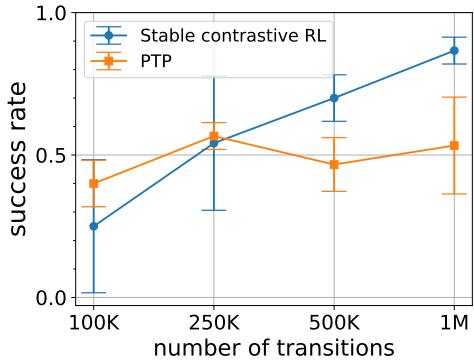

Figure 8: **The influence of dataset size.** Increasing the amount of offline data boosts the success rate of stable contrastive RL, while the performance of PTP saturates after 250,000 transitions.

Increase the success rate that increases by 3 $\times$  as we increase the dataset size. In contrast, the performance of PTP saturates around 250K transitions, suggesting that most of the gains observed for stable contrastive RL may be coming from better representations, rather than from a better reactive policy. In Appendix E.5, we also find that the binary accuracy of the stable contrastive RL (measured on predicting the future) increases with dataset size, suggesting that the method benefits from a more diverse pool of positive and negative examples.

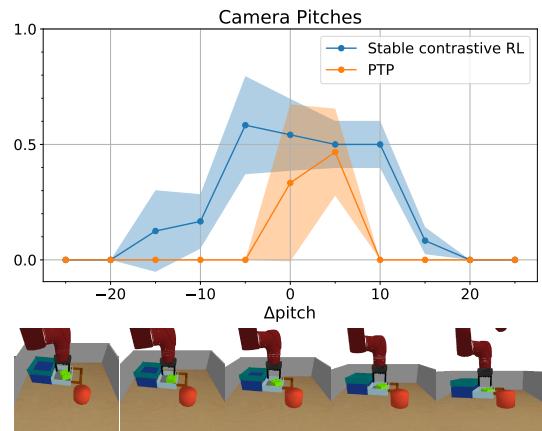

Figure 9: **Generalizing to unseen tasks.** Stable contrastive RL re-trains good performance on a broad range of unseen camera angles (pitch). Appendix Fig. 19 shows similar generalization capabilities for variations in yaw and object color.

**Additional Experiments.** In Appendix E.7 & E.8 we study the effect of augmenting stable contrastive RL with auxiliary objectives and sub-goal planning. These components are critical for PTP but decrease performance of stable contrastive RL.

## 6 Conclusion

In this paper, we have studied design decisions for a contrastive, self-supervised RL method. We have found that certain decisions regarding the architecture, batch size, normalization, weight initialization, and augmentation are all important. These design decisions were motivated by our theoretical observation that contrastive RL methods should implicitly perform a sort of hard negative mining, evincing why these methods may be useful and offering a theoretical justification for the explicit negative mining performed by prior work. Taken together, these results have allowed us to start applying these methods to real robotic manipulation tasks, and have shown that effectively-implemented contrastive RL methods have intriguing, emergent representations.

**Limitations.** Much of the motivation behind goal-conditioned RL is that it will allow RL researchers to realize the same sorts of scaling laws seen in self-supervised methods for computer vision [116] and NLP [51]. Our work is only a small step in this direction; relative to the model sizes and dataset sizes in NLP and CV, ours are tiny. However, our design decisions do allow us to significantly improve performance in the offline setting (Fig. 1) and do yield a method whose success rate seems to increase linearly as the dataset size doubles (Appendix Fig. 18). So, we are optimistic that these design decisions may provide helpful guidance on further scaling these methods.

**Acknowledgements.** We thank Ravi Tej for discussions about this work, and anonymous reviewers for providing feedback on early versions of this work. We thank Seohong Park for finding issues in the environment implementation. BE is supported by the Fannie and John Hertz Foundation and the NSF GRFP (DGE2140739). Figure 10: **Overview of network architecture.** Our experiments suggest that this architecture can stabilize and accelerate learning for contrastive RL. Layer normalization is applied to each layer of the visual feature extractor (CNN) and contrastive representations (MLP). We initialize weights in final layers of MLP close to zero to encourage alignment of contrastive representations, and use data augmentation to prevent overfitting.

## A Comparison of Related Work

We compare prior works focusing on goal-conditioned RL, representation learning, and model learning in Table 1.

Table 1: Self-supervised RL from offline data.

	Reward-free	Avoids Predicting Pixels	Directly produces a policy
Contrastive RL	✓	✓	✓
Representation Learning	✓	✓/✗	✗
Model Learning	✓/✗	✗	✗

## B Review of TD Contrastive RL

The recursive definition of the discounted state occupancy measure (Eq. 1) allows us to rewrite Eq. 2 into a *temporal different* (TD) variant [22], with  $w(s, a, sf) \triangleq \frac{\sigma(f(s, a, sf))}{1 - \sigma(f(s, a, sf))}$

$$\max_f \mathbb{E}_{\substack{(s, a) \sim p(s, a), s' \sim p(s'|s, a) \\ s_f \sim p(s_{t+}), a' \sim \pi(a'|s, a, g)}} \left[ (1 - \gamma) \log \sigma(f(s, a, s')) + \log(1 - \sigma(f(s, a, sf))) + \gamma [w(s', a', sf)]_{\text{sg}} \log \sigma(f(s, a, sf)) \right]. \quad (3)$$

A prototypical example of this TD variant is C-Learning [22] that lies in the family of contrastive RL methods [24]. We will focus on the TD learning critic objective in our discussion and adapt it to the offline setting with a goal-conditioned behavioral cloning regularized policy objective:

$$\max_{\pi(\cdot | \cdot, \cdot)} \mathbb{E}_{p_g(g)p(s, a_{\text{orig}})\pi(a|s, g)} [(1 - \lambda) \cdot f(s, a, g) + \lambda \log \pi(a_{\text{orig}} | s, a)]. \quad (4)$$

## C Architecture Diagram

An overview of our network architecture is shown in Fig. 10.

## D Experimental Details

**Tasks.** Our experiments use a suite of simulated and real-world goal-conditioned control tasks based on prior work [19, 25, 26, 65]. *First*, we use a benchmark of five manipulation tasks proposed in [25, 26] (Fig. 2). The observations and goals are  $48 \times 48 \times 3$  RGB images of the current scene. These tasks are challenging benchmarks because solving most of them requires multi-stage reasoning. *Second*, we use the goal-conditioned locomotion benchmark proposed in [65]. The observations and goal poses are  $64 \times 64 \times 3$  RGB images.

This benchmark helps study those design decisions for offline goal-reaching beyond manipulation. *Third*, we study the performance of our algorithm in real-world using a 6-DOF WidowX250 robot arm. We use Bridge dataset [19] where observation and the goal are  $128 \times 128 \times 3$  RGB images with much noisier backgrounds than the simulated tasks. For evaluation, we use three tasks from Toy Kitchen 2 scene in the dataset where the initial and desired object positions are unseen during training (see Fig. 5). These tasks are challenging because they require multi-stage reasoning (e.g., the drawer can only be opened after the orange object has been moved).

**Offline dataset.** The offline manipulation dataset we used in simulation consists of near-optimal demonstrations of primitive behaviors, such as opening the drawer, pushing blocks, and picking up objects. The scripted data collection policy can access the underlying object states. The lengths of demonstration vary from 50 to 100 time steps and the offline dataset approximately contains 250K transitions in total. We note that none of the offline trajectories complete the demonstration from the initial state to the goal. For evaluation, we create a dataset of 50 goals by randomly sampling the positions of objects and the robot arm, and evaluate the success rate of reaching these goals. The locomotion benchmark includes a mixture of optimal and suboptimal transitions. We randomly collect 100K transitions from the replay buffer of a policy trained with LEXA [65], which achieves success rates of 75% on Walker and 58% on Quadruped at convergence. Our real-world offline dataset uses the existing Bridge Data [19], including around 20K demonstrations of various manipulation skills. Note that some trajectories in this dataset are suboptimal since they were collected by a weakly scripted data collection policy that sometimes misses grasping the target objects. This dataset provides broad and diverse demonstrations to evaluate whether an agent is able to stitch skills and generalize to different scenes.

**Baseline implementations.** We use the open-sourced PyTorch [73] implementation of PTP<sup>2</sup> as our baseline and adapt the underlaying IQL algorithm to GC-IQL and GCBC. Unless otherwise mentioned, we use same hyperparameters as this implementation.

**Hyperparameters and computation resources.** We implement stable contrastive RL using PyTorch again on top of the public PTP codebase. Our algorithm is adapted from contrastive RL implementation<sup>3</sup> and incorporate those novel design decisions mentioned in Sec. 5.2. We summarize hyperparameters in Table 2. For each experiment, we allocated 1 NVIDIA V100 GPU and 64 GB of memories to do computation.

Table 2: Hyperparameters for stable contrastive RL.

Hyperparameters	Values	Notes
batch size	2048	
number of training epochs	300	
number of training iterations per epoch	1000	equivalent to number of gradient steps per epoch
dataset size	250K	number of transitions $(s, a, s', s_f)$
image size	$48 \times 48 \times 3; 128 \times 128 \times 3$	Size of RGB images in the simulated and real-world tasks
episode length	400	
image encoder architecture	3-layer CNN	kernel size = (8, 4, 3), number of channels = (32, 64, 64), strides = (4, 2, 1), paddings = (2, 1, 1)
policy network architecture	(1024, 4) MLP	
critic network architecture	(1024, 4) MLP	
weight initialization for final layers of critic and policy	UNIF $[-10^{-12}, 10^{-12}]$	
policy stand deviation	0.15	
contrastive representation dimension	16	
data augmentation	random cropping	replicating edge pixel-padding size = 4
augmentation probability	0.5	applying random cropping to both $s$ and $g$ in the GCBC regularizer in Eq. 4 with this probability
discount factor	0.99	
learning rate of Adam [52] optimizer	0.0003

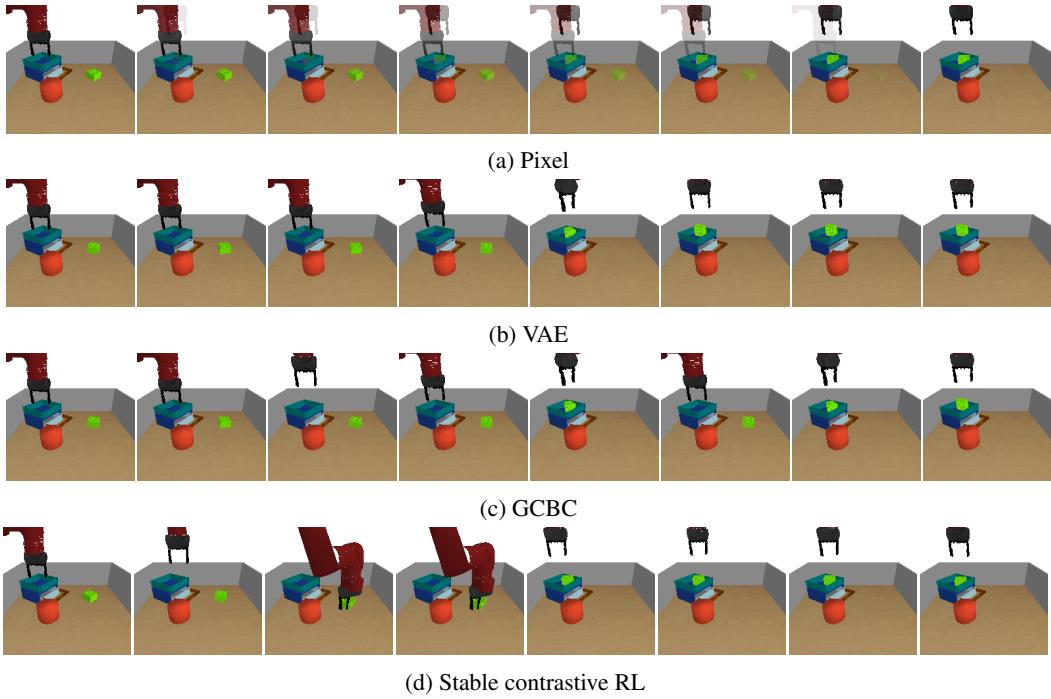

Figure 12: Interpolation of different representations on `pick & place (table)`.

## E Additional Experiments

### E.1 More Examples of Latent Interpolation

We show more examples of interpolating different representations on tasks `drawer`, `pick & place (table)`, and `pick & place (drawer)` in Fig. 11, Fig. 12, and Fig. 13 respectively.

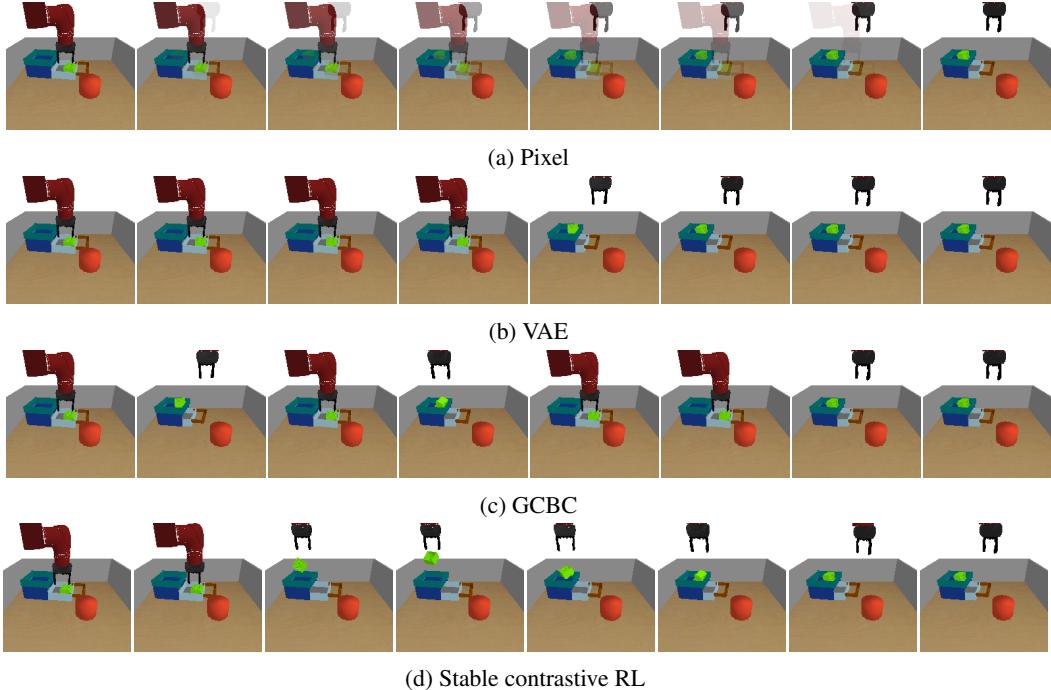

Figure 13: Interpolation of different representations on pick & place (drawer).

## E.2 Measuring Interpolation

To quantitatively study interpolation, we run another set of experiments comparing the similarity of interpolated representations (images) with the ground truth sequence. Specifically, we retrieve the nearest neighbor of each interpolated representation from a policy rollout and label the time step of interpolations accordingly ( $\text{perm}[t]$ ). With these time steps, we define a permutation error with respect to the ground truth time steps:

$$\sum_{t=0}^T |\text{perm}[t] - t|$$

Results in Fig. 14 demonstrate that interpolation in the VAE representation space and the pixel space are not well-aligned with the ground truth time steps (better than random permutations), while contrastive representations achieves a lower error, suggesting that it might contain information that is uniquely well-suited for control and potentially leverage a goal-conditioned policy.

## E.3 Arm Matching

To evaluate the performance of contrastive RL in tackling the arm matching problem, we collect a trajectory of contrastive RL trained on the offline dataset and comparing the Q value predicted by stable contrastive RL with a GC-IQL trained on top of VAE representations, assuming that pre-trained features might help mitigate the arm matching problem as well. We normalize both Qs by values of the minimum and the goal. As shown in Fig. 15, stable contrastive RL correctly learns a monotonic increasing Q throughout the rollout, while GC-IQL learns a V-shape Q relating higher values to a closer arm to the target position, ignoring the position of the green block ( $t = 30$ ). This experiment demonstrates that representations derived from VAE may be less efficient at predicting success than contrastive representations in the scene involving temporal-extended reasoning.

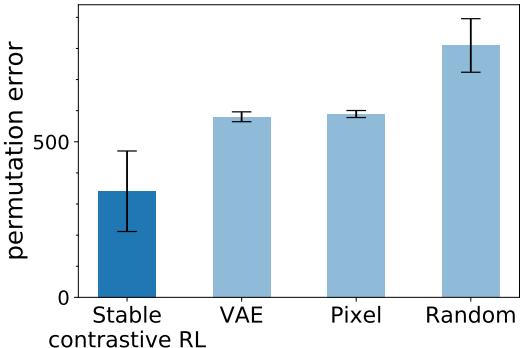

Figure 14: To quantitatively evaluate interpolation, we measure the similarity of the retrieved representations with the ground truth sequence. Stable contrastive RL achieves lower error than the alternative methods. See text for details.

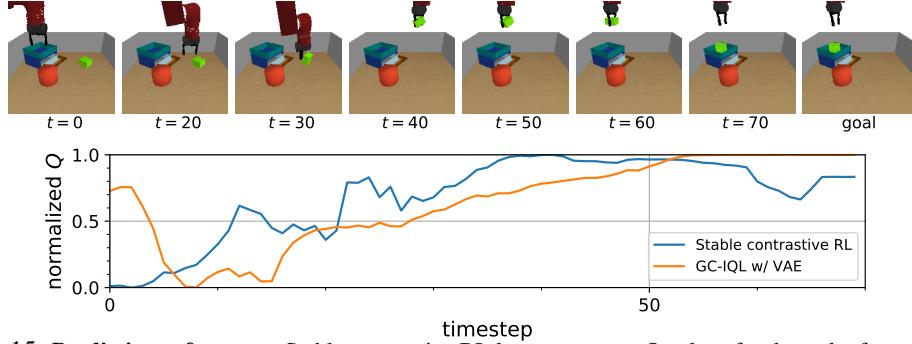

Figure 15: **Predictions of success.** Stable contrastive RL learns accurate Q values for the task of reaching the goal shown above: they increase throughout a successful rollout. On the contrary, the GC-IQL baseline mistakenly predicts that picking up the green object *decreases* the Q-value, likely because the GC-IQL representations ignore the position of the green block. This experiment suggests that representations derived from a VAE, like those learned by GC-IQL and many prior methods [68, 70, 112], may be less effective at predicting success than those learned by contrastive RL methods.

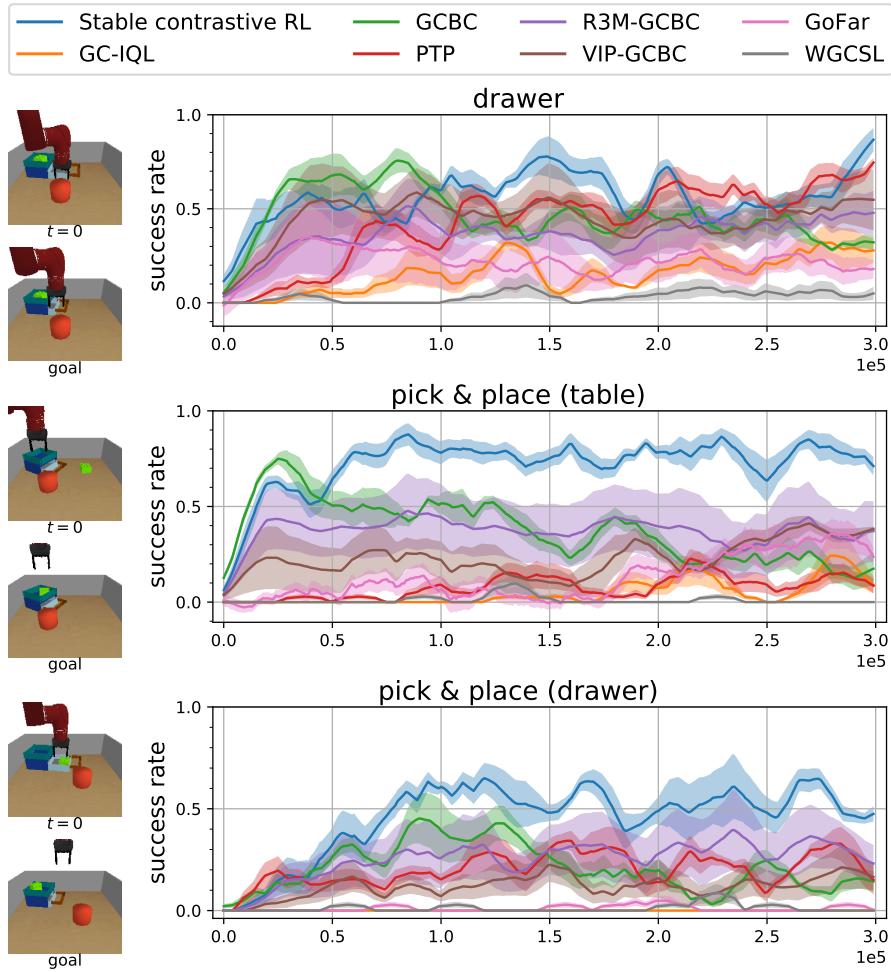

Figure 16: **Evaluation on simulated manipulation tasks.** Stable contrastive RL outperforms all baselines on drawer, pick & place (table), and pick & place (drawer).

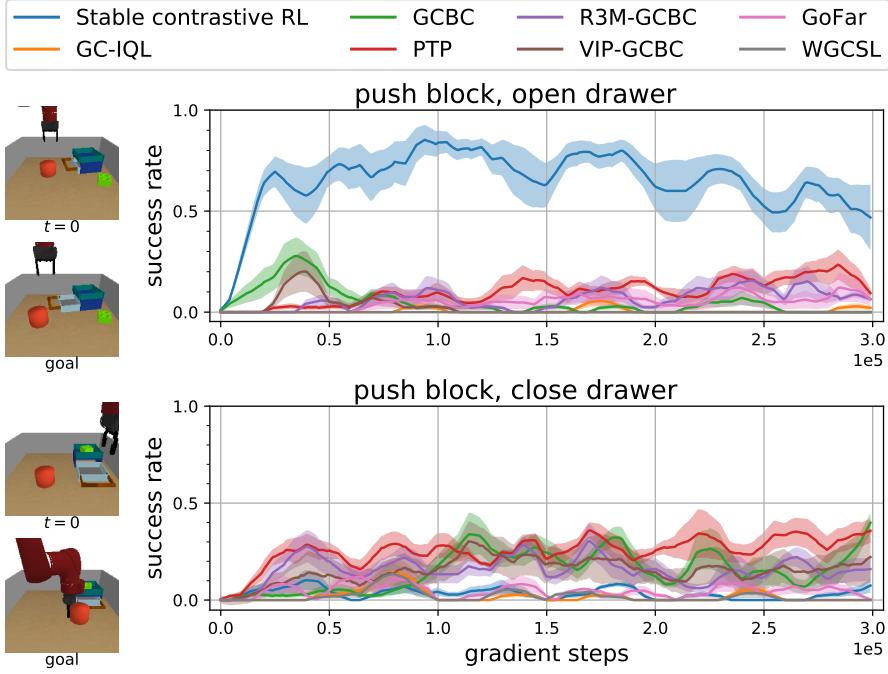

Figure 17: **Evaluation on simulated manipulation tasks.** Stable contrastive RL outperforms or performs similarly to all baselines on push block, open drawer and push block, close drawer.

#### E.4 Evaluation on simulated manipulation tasks

We report results in Fig. 16 and Fig. 17 with curves indicating mean success rate and shaded regions indicating standard deviation across 5 random seeds after 300K gradient steps’ training. Stable contrastive RL outperforms or achieves similar performance on 4 out of 5 tasks comparing to other baselines. These results suggest that when accompanied with proper techniques, stable contrastive RL is able to leverage a diverse offline dataset and emerges a general-purpose goal-conditioned policy, thus serving as a competitive offline goal-conditioned RL algorithm.

#### E.5 Dataset Size

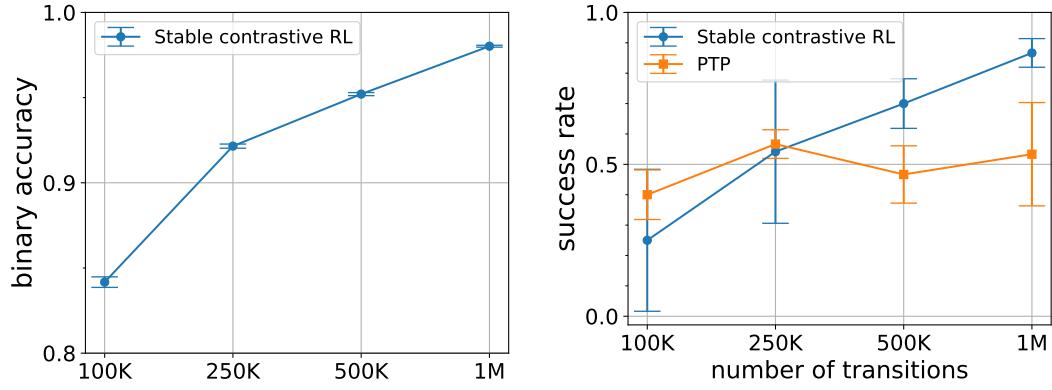

Figure 18: Increasing the amount of offline data improves the binary future prediction accuracy of stable contrastive RL and boosts the success rate.

Scaling model performances with the amount of data have been successfully demonstrated in CV and NLP [7, 44], motivating us to study whether contrastive RL offers similar scaling capabilities in the offline RL setting. Sec. 3.2 have discussed the benefits of training with more positive and negative pairs to contrastive representation learning, suggesting that increasing amounts of data might also boost the performance of contrastive RL. We empirically

study the hypothesis that *stable contrastive RL* learns a representation that achieves better performances with growing dataset size.

To test this hypothesis, we create datasets of different sizes containing various manipulation skills, select task `drawer` for evaluation, and compare the accuracy of stable contrastive RL in predicting future states on each of the datasets. We compare stable contrastive RL against PTP that is based on a pre-trained VAE. We compare both algorithms by training three random seeds of them for 300K gradient steps on each dataset. Fig. 18 shows the mean and standard deviation of success rates over 10 rollouts and binary future prediction accuracies computed between critic outputs and ground truth labels. Observe that when the size of dataset *increased*, the binary accuracy of contrastive RL *increase* accordingly ( $84\% \rightarrow 98\%$ ), suggesting that the algorithm indeed strengthens its representation in future prediction. These results make sense, as increasing the size of the dataset is especially important for contrastive approaches that directly use all of the data as *negative* examples. In addition, our experiments show that contrastive RL consistently improves its success rates when we use larger dataset:  $31\% \rightarrow 84\%$ , verifying our hypothesis. We suspect that the emerging of a denser distribution of positive and negative pairs given a larger dataset might facilitate policy learning. In contrast, a steady or even lower success rate of PTP given the increasing amounts of data might due to the capacity limitation of pre-trained VAE representation.

## E.6 Generalization

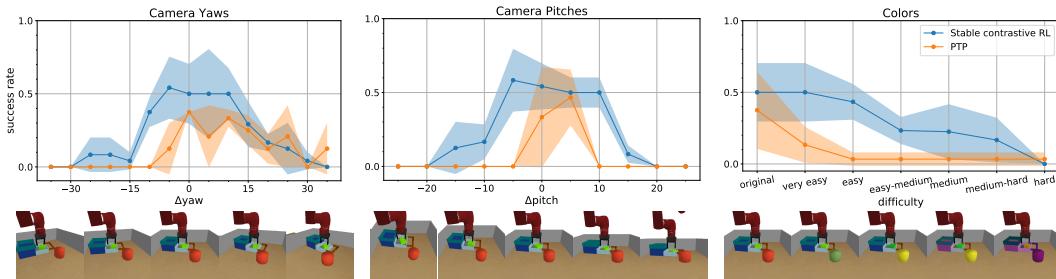

Figure 19: **Generalizing to unseen tasks.** Stable contrastive RL retrain good performance on a broad range of unseen camera angles (yaws / pitches) and object colors.

One of the drawbacks of driving RL by pre-trained visual representation learning is tying algorithm performance with the latent representation to reconstruct corresponding images. Figure 6 has shown the *support* of VAE representation distribution could be discontinuous and there could be noise in a out-of-distribution reconstructed image, indicating the degradation of RL performance on unseen tasks. Rather than predicated on a pre-trained visual representation, stable contrastive RL trains its self-supervised representation with the actor-critic framework [24], expecting to acquire a more robust and generalizable algorithm. We hypothesize that *stable contrastive RL generalizes better to unseen tasks than prior method*.

To test this hypothesis, we ran experiments with one of our goal-conditioned tasks in three visually different scenarios (Fig. 19): varying the camera yaw angle, varying the camera pitch angle, and varying the color of objects in the scene. We evaluate the policy of stable contrastive RL and PTP after 300K gradient steps' offline training in these three scenarios, plotting the mean and standard deviation of success rate across three random seeds. Since the color of objects cannot be quantified precisely, we change colors of one to several objects and define the difficulty of each scene accordingly. As shown in Fig. 19, PTP is highly sensitive to both camera viewpoints and object colors: large values of camera  $\Delta\text{yaw}$  and  $\Delta\text{pitch}$  and significant different object colors result in uninformative VAE representation, PTP consequently performs poorly. Stable contrastive RL, which does not depend on VAE representation, outperforms PTP and is robust to a wide range of camera angles and object colors. These experiments provide preliminary evidence that contrastive representations might generalize reasonably well.

## E.7 Additional Perceptual Losses

Prior work has found that auxiliary visual loss is necessary and important to drive an RL algorithm [112]. However, visualization and analysis in Fig. 6 suggest that stable contrastive RL is already acquiring useful representations, leading us to hypothesize that it may not require additional perception-specific losses. To test this hypothesis, we compare contrastive RL (with representations learned end-to-end) with a variant that uses a pre-trained VAE representation as the input for both actor and critic. We compare against PTP (which uses the same VAE representation) and an end-to-end variant of PTP. We use the task `push block`, `open drawer` for these experiments, as it demands the most temporally-extended reasoning to solve.

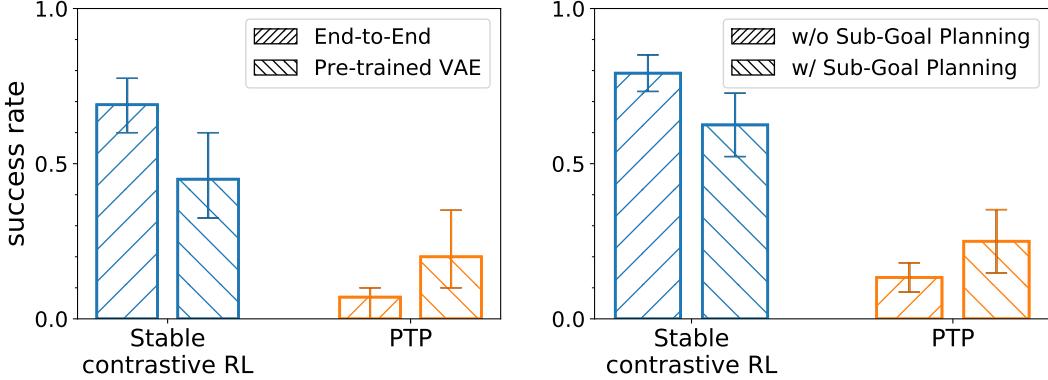

Figure 20: (Left) Additional perceptual losses are not needed for stable contrastive RL to outperform PTP. (Right) Without sub-goal planning, stable contrastive RL can solve temporal-extended tasks.

We compare all methods by training three random seeds of each of the four methods for 300K gradient steps on the offline setting. We measure performance by evaluating each seed in 10 rollouts. Fig. 20 (Left) shows the mean and standard deviation of these results. First, we find that stable contrastive RL achieves 53% higher success rates than the VAE-based version of contrastive RL, showing that contrastive RL does not require a perception specific loss, and instead suggesting that a good representation emerges purely from optimizing the contrastive RL objective. Intuitively, this result makes sense, as the contrastive RL critic objective already resembles existing representation learning objectives. The observation that adding the VAE objective *decreases* performance might be explained by the misalignment between the VAE objective and the contrastive RL objective – directly optimizing the representations for the target task (learning a critic) is better than optimizing them for reconstruction (as done by the VAE). We conjecture that VAE representation could contain task-irrelevant noise that impairs policy learning. Second, we find that the VAE objective is important for the prior method, PTP; removing the VAE objective and learning the representations end-to-end decreases performance by 55%. This result supports the findings of the original PTP paper [25], while also illustrating that good representations can be learned in an end-to-end manner if the RL algorithm is chosen appropriately.

### E.8 Sub-goal planning

Goal-conditioned RL often requires the agent to reason over long horizons. Prior works has proposed to combine critic learning with an explicit planner [23, 25, 82], using the learned value network as distance function to generate sub-goals. These *semi-parametric* methods can work really well in practice, but it remains unclear why *fully-parametric* model-free GCRL algorithms failed to perform similarly given the same training data. We have shown that stable contrastive RL learns a representation preserving causal information (Fig. 6) and a policy rearranging representations in temporal order (Fig. 15). So *can fully-parametric methods achieve comparable or better performance to semi-parametric methods with proper design decisions?*

To answer this question, we compare stable contrastive RL (a fully-parametric algorithm) with a variant that use explicit sub-goal planning. We compare against PTP (a semi-parametric method) and a variant of PTP without sub-goal planning. To make a fair comparison, we apply the same planning algorithm of PTP to the variant of stable contrastive RL. We choose the task pick & place (table) which requires the agent to pick and place a block to conduct our experiments. We train three random seeds of all the four methods for 300K gradient steps with the same offline dataset and evaluate the success rate over 10 rollouts, reporting the mean and standard deviation across seeds.

As shown in Fig. 20 (Right), stable contrastive RL achieves a 30% absolute improvement over its semi-parametric variant, suggesting that stable contrastive RL does not require planner and, surprisingly, sub-goal planning could *hurt* the performance. We suspect that the policy can find a path in representation space that corresponds to an optimal trajectory in state space without additional supervision. The reason for adding planning module *decrease* performance might be explained by the fact that self-supervised critic objective does not imply a distance measure between the current state and the goal, and the growing computational complexity of planning. We observe that sub-goal planning is critical to improve the performance of PTP by 50%, which is consistent with the claim in the original PTP paper [25]. Nonetheless, neither version of PTP achieves comparable results to stable contrastive RL, showing that semi-parametric methods might not do well in a task with causal reasoning. Taken together, these experiments suggest that, with proper design decisions, a fully-parametric method like stable contrastive RL can at match (if not surpass) the performance of more complex semi-parametric methods that employ planning.

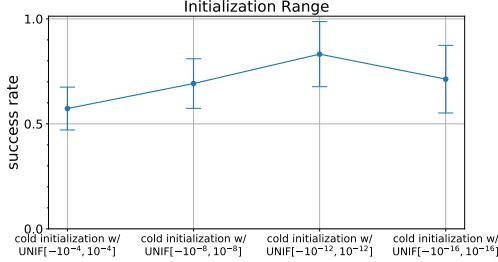

Figure 23: Smaller cold initialization (in a certain range) improves the performance of stable contrastive RL.

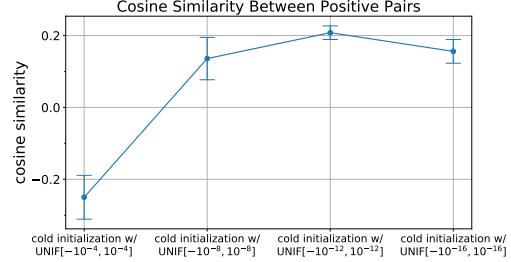

Figure 24: A fairly small cold initialization value encourages alignment.

### E.9 Ablation Experiments: Batch Size

These ablation experiments test whether the batch size can affect the performance of stable contrastive RL and whether an ever larger batch size can induce an ever improvement in performance. To answer these questions, we vary the batch size from 512 to 4096 during training of stable contrastive RL and find the performance follows the batch size increasing paradigm as expected. However, the improvement stops after a certain threshold, indicating there might be other factors, e.g. network capacity and training steps [11], that dominate the performance after a batch size limit.

### E.10 Ablation Experiments: Cold Initialization

We run additional experiments to study whether cold initialization provides similar performance gains as learning rate schemes. We compare three methods: (a) cold initialization as mentioned in Sec. 3.2, (b) learning rate warmup, following the same warmup paradigm in [101] – linearly increasing the learning rate to  $3 \times 10^{-4}$  for the first 100K gradient steps and then decreasing it proportionally to the inverse square root of remaining gradient steps. (c) using a  $10\times$  smaller learning rate for the last layers of  $\phi(s, a)$  and  $\psi(g)$ . Our new experiments (Fig. 22) find that both (b) and (c) consistently perform worse than cold initialization.

To get a better understanding of the mechanism of cold initialization, we hypothesize that the range of initialization will affect the performance of stable contrastive RL. We conducted ablation experiments with initialization strategies  $\text{UNIF}[-10^{-4}, 10^{-4}]$ ,  $\text{UNIF}[-10^{-8}, 10^{-8}]$ ,  $\text{UNIF}[-10^{-12}, 10^{-12}]$ , and  $\text{UNIF}[-10^{-16}, 10^{-16}]$  for the final layers of  $\phi(s, a)$  and  $\psi(g)$ , plotting the success rates over 10 episodes and 3 random seeds in Fig. 23. The observation that small initialization ranges tend to perform better, with a value of  $10^{-12}$  achieving 45% higher success rate than a (more standard) range of  $10^{-4}$ , is consistent with our expectation that a fairly small initialization range incurs better performance. We note that the performance of the range  $10^{-16}$  is  $0.857\times$  (71.3% vs. 83.2%) than that of the range  $10^{-12}$ , suggesting that an ever decreasing initialization range start to hinder representation learning after a certain value.

One effect of the cold initialization is that it changes the average distance between representations at random initialization. We next measure the average pairwise (cosine) distance between representations, for different initialization ranges. We randomly sample 10 validation batches and compute the average cosine similarities of positive pair at initialization as a function of different cold initialization ranges, showing results in Fig. 24. The finding that cosine similarities between positive examples decrease when we vary the initialization ranges from  $10^{-4}$  to  $10^{-12}$  explains the intuition that alignment between positive examples is crucial to contrastive representation learning. Of particular note is that using a very small initialization range  $10^{-16}$  could force all representations to collapse, resulting in a worse performance. We observe that initialization strategies for which the representations are closer (higher cosine similarity) also result in higher success rates after training. This

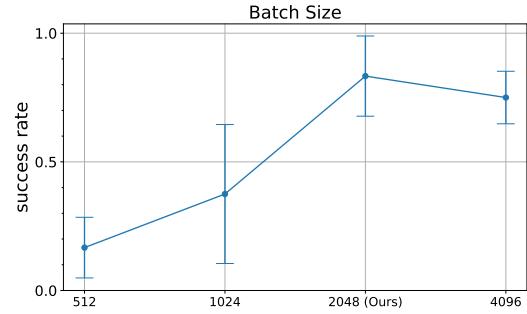

Figure 21: Larger batch size (in a certain range) improves the performance of stable contrastive RL.

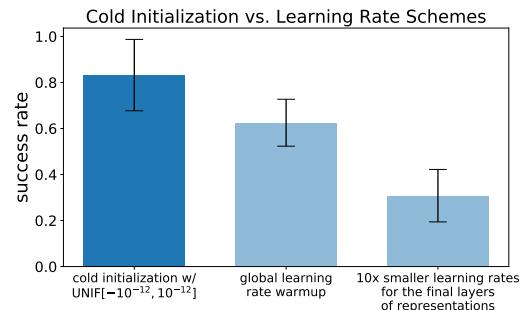

Figure 22: Cold initialization is more effective than learning rate schemes for stable contrastive RL.

suggests that the average pairwise distance at initialization may be an effective way of selecting the initialization range *that does not require performing any training*.

### E.11 Ablation Experiments: Contrastive Representation Dimension

While we used small representations (16 dimensional) in the main experiments, we now study how increasing the representation dimension affects the success rates. We ablate the dimension of contrastive representation in the set {16, 128, 512}, averaging success rates over 10 episodes of 3 random seeds. As shown in Fig. 25, representations of sizes 128 and 512 achieve considerably lower success rates, echoing prior work in finding that smaller representations yield better performance in the offline setting [24]. These results might also be explained by the increase of noise with a larger representation size, suggesting that the smaller representations effectively act as a sort of regularization and mitigate overfitting.

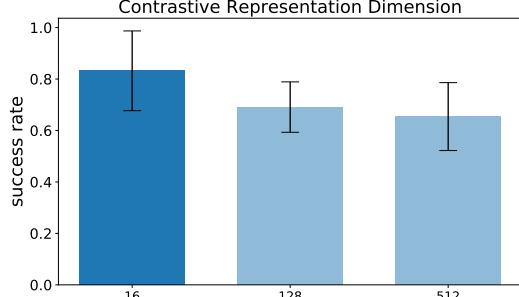

Figure 25: Smaller representation dimension benefits the learning of stable contrastive RL.
